Effects of Surface Dehydration on Mucosal Wave Amplitude and Frequency in Excised Canine Larynges

Rachel E. Witt¹, Lindsay N. Taylor¹, Michael F. Regner¹, and Jack J. Jiang, MD, PhD¹

Abstract

Objective. Evaluate the effect of vocal fold surface dehydration on mucosal wave amplitude and frequency.

Study Design. Controlled test-retest.

Setting. Larynges were mounted on an excised larynx phonation system and attached to a pseudolung in a triple-walled sound-attenuated room that eliminated background noise and maintained a stabilized room temperature and humidity level.

Subjects and Methods. High-speed video was recorded for 8 excised canine larynges during exposure to dehumidified air at 20 cm H₂O. Control trials consisted of high-speed videos recorded for 2 excised canine larynges during exposure to humidified air at the same pressure.

Results. In the majority of larynges, increased levels of dehydration were correlated with decreased amplitude and frequency. The slope of the linear regression fitted to the change in amplitude (P = .003) and the percent change (P < .001) between the initial and final trials were significantly decreased in dehydrated larynges. These measurements with respect to the change in frequency were also significantly decreased in dehydrated larynges (P < .001; P = .027).

Conclusion. Vocal fold surface dehydration caused a decrease in mucosal wave amplitude and frequency. This study provides objective, quantitative support for the mechanism of voice deterioration observed after extreme surface dehydration.

Keywords

excised larynx, dehydration, mucosal wave

During phonation, the passage of air from the lungs through the glottis causes oscillation of the vocal folds at a certain frequency for a given glottal configuration. This transduction of energy from pulmonary airflow into vocal fold vibration in turn results in pulsatile airflow that is the sound source. The mucosal wave during normal phonation is best characterized as a symmetrical transverse wave along the mucosal margin in the sagittal plane. It propagates from the inferior margin of the folds and subsequently travels superiorly to the superior margin of the folds. Changes in the mass, viscosity, length, or tension of the lamina propria may cause abnormalities in the propagation of the mucosal wave. Previous studies have manipulated the viscosity of the lamina propria by applying artificial mucous to the vocal folds, resulting in quantitative changes in the mucosal wave. Increased viscosity was correlated with increased contact phase of the glottic cycle and decreased vibratory frequency, amplitude, and open quotient of the glottic cycle.

Stiffness and viscosity of the lamina propria can also increase with dehydration of the vocal folds. Changes in phonatory parameters observed after vocal fold dehydration are similar to those observed after the application of viscous fluid to the vocal fold; therefore, voice deterioration following dehydration has been attributed to changes in biomechanical properties such as viscosity. The amount of energy dissipated due to friction in the oscillating vocal folds increases with viscosity, and thus more aerodynamic energy is required to maintain the same phonatory conditions in dehydrated vocal folds. Presumably by causing increased viscosity of the vocal fold mucosa, dehydration has been shown to increase phonation threshold pressure (PTP) and phonation threshold flow (PTF), both of which indicate the "ease of phonation." These trends have been observed at the systemic, tissue, and mucosal surface levels of dehydration.

The effects of increased viscosity on mucosal wave characteristics have been quantified using electrogastrography (EGG), laryngostroboscopy, and X-ray stroboscopy. EGG represents mucosal wave as a waveform of electrical impedance that describes the time-varying relative vocal fold contact area patterns within the glottal cycle. However, EGG waveforms are easily confounded by normal variations, such as mucus that spans the width of the glottis, so it may provide inconsistent measurements of frequency and glottis cycle. Measurements of the mucosal wave using stroboscopy may not accurately characterize an aperiodic mucosal wave because this technique creates a composite image of the mucosal wave averaged over several cycles. Among other causes, abnormal vibrations may be associated with extreme changes in lamina propria physiology induced by dehydration. The advent of high-speed digital imaging (HSDI) has provided a more accurate method of mucosal wave visualization because it provides real-time visualization at frequencies much higher than those of phonation. HSDI has been found to produce significantly more accurate and interpretable images of the mucosal waves of pathological larynges than stroboscopy.

By inducing dehydration in the lamina propria of the vocal folds, this study contributes quantitative support for inferred mechanisms of voice deterioration due to dehydration and may provide reference for clinical evaluation. With the increased use of high-speed video to visualize the mucosal wave, measurement and analysis of vocal fold oscillation are necessary to evaluate and refine current theories of voice production. This study provides pertinent estimates of the mucosal wave for patients suffering from dehydration.

**Methods**

**Larynges**

In this excised study, the sample population consisted of 10 excised canine larynges. The larynges were obtained immediately postmortem from canines that died from causes unrelated to this study. Approval from an institutional review board was not necessary because no humans were involved, and approval from an animal care and use committee was not required because the animals were not sacrificed for the present study. The larynges were excised according to the procedure described by Jiang and Titze, and they were subsequently examined to ensure the absence of diseased tissue or lesions. The larynges were immediately placed in a 0.9% saline solution and quickly frozen for later use, whereupon they were thawed slowly.

**Apparatus**

The epiglottis, cuneiform cartilages, corniculate cartilages, and ventricular folds were dissected away to expose the vocal folds immediately prior to experimentation. The superior cornua and the superior portions of the thyroid cartilage were also removed to facilitate the insertion of lateral micrometers into the arytenoid cartilages during the trials. The larynges were mounted on an excised larynx phonation system, as shown in Figure 1. A small segment of the trachea inferior to the larynx was clamped to a pipe using a hose clamp. The pipe was connected in series to 2 ConchaTherm III heater-humidifiers (Fisher & Paykel Healthcare, Inc, Laguna Hills, California), and an Ingersoll Rand (type 30; Ingersoll Rand, Dublin, Ireland) air compressor controlled subglottal pressure. Two 3-pronged micrometers were inserted into the lateral aspects of the arytenoids, controlling vocal fold adduction and abduction at the point of glottal closure. The elongation of the vocal folds was controlled by another micrometer system sutured to the anterior commissure of the thyroid cartilage. The length of the vocal folds was measured for calibration purposes. The elongation of the vocal folds remained constant throughout all trials.

All measurements were taken in a triple-walled sound-attenuated room that eliminated background noise and maintained a stabilized room temperature and humidity level. A high-speed digital camera (Fastcam-ultima APX) was mounted on a track system above the vocal folds. This camera recorded the vocal fold vibrations at a rate of 4000 frames per second and at a resolution of 256 × 512 pixels.

**Experimental Procedure**

For the 8 dehydration trials, warm, nonhumidified air between 36°C and 38°C and 25% ± 3% relative humidity was directed through the vocal folds at a constant pressure of 20 cm H_2O until the larynges ceased to phonate. No saline solution was applied to the larynges during the trials. During phonation, the camera was automated to take 768 frames of high-speed video, initially every 60 seconds. When phonation became more irregular than its initial quality, the camera’s automation was adjusted to record every 10 seconds. Videos were recorded until the larynx ceased to phonate at 20 cm H_2O.

**Control Trials**

During the 2 control trials, warm, humidified air of about 36°C to 38°C and 100% relative humidity was directed through the vocal folds at a constant pressure of 20 cm H_2O for 30 minutes. The larynges were kept hydrated throughout the 30 minutes of phonation with applications of 0.9% saline solution at 30-second intervals. During the 30 minutes of phonation, the camera was automated to take 800 frames of high-speed video every 60 seconds.

**Data Analysis**

The HSDI recordings of the mucosal wave were analyzed using a custom MATLAB program (The MathWorks, Natick, Massachusetts), and the mucosal wave characteristics of each of the 4 vocal fold lips (right-upper, right-lower, left-upper, left-lower) were quantified via digital videokymography (VKG). Threshold-based edge detection, manual wave segment extraction, and nonlinear least squares curve fitting using a Fourier series were applied to the VKG to determine the most closely fitting sinusoidal curve. The coefficients of the wave function for this curve were used to derive the amplitude and frequency of each vocal fold lip in the control and dehydration trials.

The slope of the linear regression fitted to the changes in amplitude and frequency over time and the percent change for these parameters were calculated for each larynx. Mann-Whitney rank sum tests were applied to the data to determine whether statistically significant differences existed between the percent
changes for amplitude and frequency in the dehydrated larynges and those in the control larynges. The Pearson product-moment correlation coefficients were also calculated for the mucosal wave data for each larynx to determine the existence and direction of correlations between dehydration level and amplitude and frequency, respectively.

Results
The results of the Mann-Whitney rank sum tests indicated the existence of a statistically significant difference between the mean slopes of the control and dehydration treatment linear regressions fitted to the changes in amplitude ($P = .003$) and frequency ($P < .001$) over time. The difference between mean percent changes in amplitude ($P < .001$) and frequency ($P = .027$) over time of the control and dehydrated groups was also statistically significant, as illustrated in Figures 2 and 3. These results are summarized in Table 1.

In the control treatment, the Pearson product-moment correlation coefficients indicated the existence of a slightly positive correlation between trial time and amplitude and a slightly negative correlation between trial time and frequency. Although changes were observable, they were small compared to those in the dehydrated larynges. The Pearson product-moment correlation coefficient between dehydration time and amplitude indicated that changes in this mucosal wave parameter also conformed to a negative linear trend in 7 of 8 larynges. The Pearson product-moment correlation coefficient between dehydration time and frequency was negative in all of the dehydrated larynges. The Pearson product-moment correlation coefficients for amplitude and frequency in both control and dehydrated larynges are provided in Table 2.

Qualitatively, decreases in the parameters of amplitude and frequency were observable between kymographic images of the control and dehydrated larynges (Figure 4).

Discussion
The present study demonstrates the effects of dehydration on the mucosal wave parameters of amplitude and frequency. In
the majority of larynges, increased levels of dehydration, modeling longer periods of air flow, were correlated with decreased amplitude and frequency. Previous studies identified the level of vocal fold hydration as a variable affecting voice quality and the aerodynamic parameters of PTP and PTF, but the relationships between dehydration and vibratory parameters have not been previously quantified. The results of the study by Chan and Tayama established a link between hydration and tissue rheology of the lamina propria; dehydration was directly related to vocal fold tissue stiffness and viscosity. The results of this study provide support for the inverse relationship between vocal fold tissue viscosity and mucosal wave amplitude and frequency.

Asterisk denotes significant P value. R value refers to Pearson product-moment correlation coefficient.

Figure 4. Kymographic images of excised larynges while hydrated (A) and after dehydration (B).
mucosal wave amplitude was observed. The slope of the linear regression fitted to the change in amplitude over time and the percent change between the amplitudes of the initial and final mucosal waves were significantly larger in the dehydrated condition than in the control condition. This decrease in amplitude during dessicating phonation may be caused by changes in the viscoelastic and biomechanical properties of the larynx. Functionally, PTP is an index of minimum energy required to initiate and vibration of the vocal folds. The energy supplied to the vocal folds by the glottal airstream at this pressure is slightly larger than the energy dissipated during phonation because of tissue damping; therefore, the oscillation of the vocal folds can become self-sustained. Dehydration is positively correlated with PTP; as the viscosity of the lamina propria increases, which can be caused by dehydration, the amount of energy lost as a result of internal friction in the folds also increases. At a constant pressure, an increasingly greater portion of the energy provided by the glottal airstream is dissipated by friction as the level of dehydration increases. Consequently, the portion of energy is expended as vocal fold oscillation decreases. Prolonged flow of dry air across the vocal folds also increases the viscosity of the mucus on the vocal fold surfaces. Ayache et al found that the application of artificial mucus to the vocal fold surface of excised porcine larynges decreased vibratory frequency and increased the duration of the contact phase, both as an absolute value and as a proportion of the duration of the total glottal cycle. Adhesion between the vocal folds may increase PTP. Nakagawa et al also observed that a similar decrease in mucosal wave amplitude after the application of artificial mucus to the vocal folds similarly increased the viscosity of the lamina propria surface. The decrease in amplitude was attributed to an increase in vocal fold superficial tension, resulting in a reduction of the velocity of the mucosal wave. The combined factors of increased vocal fold tissue viscosity and mucus viscosity in the dehydrated excised canine larynges result in impaired aerodynamic parameters. In the present study, dehydration of the surface epithelia of the lamina propria was induced by exposing the vocal folds to constant dry airflow at a constant pressure of 20 cm H2O. As the level of dehydration increased, it is likely that PTP also increased until it reached and surpassed 20 cm H2O. The decrease in the energy expended in sustaining vocal fold oscillation resulted in continuously decreasing mucosal wave amplitude.

A statistically significant negative correlation was also observed between the level of dehydration and mucosal wave frequency across all dehydrated larynges included in this study. Ayache et al determined that vibratory frequency decreased after the application of viscous artificial mucus to the vocal fold surface. The decrease in frequency associated with high viscosity was also correlated with an increase in contact time between the vocal folds during the glottal cycle. Similarly, increased viscosity of the lamina propria due to dehydration appears to result in increased superficial tension, which causes prolonged contact between the vocal folds.

The decreases observed in mucosal wave amplitude and frequency during the present study are consistent with those of previous studies in which the viscosity of the mucosal wave was increased by the application of artificial mucus. In the present study, the viscosity of the lamina propria was similarly increased by superficial dehydration. The literature and present study suggest that the effects of increased tissue viscosity on mucosal wave characteristics appear to be independent of the method of dehydration. Although small changes were observed in amplitude and frequency observed in the control trials, these may have been caused by slight alterations in glottal configuration during prolonged exposure to airflow or some minimal level of tissue desiccation. Glottal configuration may be affected by changes in the volume of the vocal folds that result from dehydration. Linear inverse relationships exist between the level of dehydration and the tissue composition parameters of the liquid mass and volume fractions and the liquid/solid mass and volume ratios. Dehydration reduces the liquid content of the vocal folds, thus decreasing their volumes. These changes would have similarly affected the dehydrated larynges.

This is the first study evaluating the effect of dehydration on amplitude and frequency using HSDI. The relationship between mucosal wave parameters and hydration has potential clinical impact, as deviations from normal values may be an indicator of possible laryngeal dysfunction. The inability to maintain normal fluid balance has been associated with several laryngeal pathologies, including lesions, nodules, and polyps. The empirical measurements of changes in mucosal wave parameters during the dehydration process provide quantitative support for the biomechanical basis of voice deterioration. Although the results of this study suggest that the dehydration of epithelial cells in ex vivo larynges causes a decrease in the amplitude and frequency of mucosal wave, future studies could measure these parameters in human subjects with the aim of quantitatively describing mucosal waves associated with different types and degrees of dehydration. The effects of rehydration on vocal fold mucosal wave parameters may also be useful in evaluating the efficacy of different hydration treatments.

Conclusion

Dehydration is negatively correlated with mucosal wave amplitude and frequency. This study provides objective, quantitative support for the mechanism of voice deterioration observed after extreme surface dehydration. Clinically, these relationships may be used to objectively determine the extent of dehydration due to desiccation or to underlying laryngeal pathologies.
