Abstract

Objective. The effect of vocal fold medialization (VFM) on vocal improvement in persons with unilateral vocal fold immobility (UVFI) is well established. The effect of VFM on the symptom of dysphagia is uncertain. The purpose of this study is to evaluate dysphagia symptoms in patients with UVFI pre- and post-VFM.

Study Design. Case series with chart review.

Setting. Academic tertiary care medical center.

Subjects and Methods. The charts of 44 persons with UVFI who underwent VFM between June 1, 2013, and December 31, 2014, were abstracted from a prospectively maintained database at the University of California, Davis, Voice and Swallowing Center. Patient demographics, indications, and type of surgical procedure were recorded. Self-reported swallowing impairment was assessed with the validated 10-item Eating Assessment Tool (EAT-10) before and after surgery. A paired samples t test was used to compare pre- and postmedialization EAT-10 scores.

Results. Forty-four patients met criteria and underwent either vocal fold injection (73%) or thyroplasty (27%). Etiologies of vocal fold paralysis were iatrogenic (55%), idiopathic (29%), benign or malignant neoplastic (9%), traumatic (5%), or related to the late effects of radiation (2%). EAT-10 (mean ± SD) scores improved from 12.2 ± 11.1 to 7.7 ± 7.2 after medialization ($P < .01$) with a follow-up of 119 ± 65 days.

Conclusion. Patients with UVFI suffer from dysphagia and report significant improvement in swallowing symptoms following VFM. The symptomatic improvement appears to be durable over time.

Glottal closure is a critical component of normal phonation and deglutition. Unilateral vocal fold immobility (UVFI) is a common cause of incomplete glottal closure and may occur as a consequence of iatrogenic vagal or recurrent nerve injury, cervical trauma, neoplasms, inflammatory processes, radiation therapy, or idiopathic causes. The resultant glottal insufficiency may lead to symptoms of dysphonia, aphony, dyspnea, decreased cough strength, and dysphagia. The detriment of UVFI on voice,¹ breathing,² and voice-related quality of life³ has been thoroughly studied. However, the prevalence of dysphagia symptoms and the pathophysiology of any underlying swallowing impairment in those with UVFI are less well defined.

UVFI has been linked with increased rates of aspiration before, during, and after the pharyngeal swallow.⁴ Multiple series suggest that up to half of those patients with UVFI will demonstrate penetration or aspiration on videofluoroscopic studies or fiberoptic endoscopic evaluation of swallowing.⁵,⁶ In addition to frank glottal incompetence, a growing body of evidence suggests that other factors, such as pharyngeal weakness⁷ and decreased sensation,⁸ may contribute to swallowing dysfunction in UVFI.

The benefits of vocal fold medialization (VFM) on voice quality and acoustic parameters have been thoroughly investigated. Vocal fold injection augmentation, whether performed under general anesthesia or in office, has a reported technical success rate of at least 97% across a number of injectable materials.⁹ There does not appear to be a significant difference between injection augmentation and medialization.
thyroplasty, and both techniques demonstrate significant improvements in perceptual, acoustic, and aerodynamic measures of voice. The effect of VFM on dysphagia in those with UVFI is less clear. Both injection medialization and type I thyroplasty have been found to improve rates of penetration and aspiration on fluoroscopy. The impact of VFM on patient-reported dysphagia has yet to be studied. The purpose of this investigation was to evaluate the effect of VFM on self-reported symptoms of dysphagia.

Methods
The charts of persons with UVFI who underwent VFM between June 1, 2013, and December 31, 2014, were abstracted from a prospectively maintained database at the University of California, Davis, Voice and Swallowing Center. Use of this database for clinical research was approved by the Institutional Review Board of the University of California, Davis. All patients with UVFI were confirmed by videolaryngoscopy and/or stroboscopy. Descriptive data were recorded, including patient demographics, etiology of UVFI, duration of UVFI, and type of surgical procedure. All patients underwent either vocal fold injection medialization with calcium hydroxylapatite or type 1 Gore-Tex thyroplasty. The time between VFM and clinic follow-up was documented.

The primary outcome measure was self-reported swallowing disability. This was assessed with the validated 10-item Eating Assessment Tool (EAT-10) before and after surgery, with scores ≥3 considered abnormal, as suggested by normative data. Scores on the 10-item Voice Handicap Index (VHI-10) described by Rosen et al served as the secondary outcome measure of self-reported voice impairment. A paired samples t test was used to compare pre-VFM EAT-10 and VHI-10 scores with post-VFM scores at the first and second follow-up visits. Comparisons between the thyroplasty and injection medialization groups as well as between the idiopathic and iatrogenic groups were made with the independent samples t test. Statistical significance was based on a type I error <5%.

Results
Forty-four patients met inclusion criteria. The etiology of UVFI was iatrogenic (55%), idiopathic (29%), benign or malignant neoplastic (9%), traumatic (5%), or related to the late effects of radiation (2%). The median duration of UVFI from symptom onset to date of surgery was 36 months, with the shortest duration recorded as 7 months. At the preoperative visit, 30 patients (68%) submitted abnormal EAT-10 scores (≥2). A total of 12 patients (27%) underwent type I thyroplasty, while the remaining 32 patients (73%) received injection medialization. Two patients participated in a swallow therapy session prior to surgery. The mean ± SD time to first follow-up visit was 28 ± 14 days. A total of 27 (61%) patients had a second follow-up visit, with a mean time to second follow-up of 119 ± 65 days.

The mean ± SD preoperative EAT-10 scores for the thyroplasty, injection medialization, and combined groups were 13.8 ± 10.7, 11.6 ± 11.5, and 12.2 ± 11.1, respectively. There were statistically significant improvements in mean EAT-10 score at the first postoperative visit in the thyroplasty (5.1 ± 3.9, P = .0127), injection medialization (8.1 ± 9.1, P = .0079), and combined (7.7 ± 8.1, P = .0001) groups. The mean EAT-10 score remained significantly improved at the second postoperative visit in the injection medialization (7.4 ± 6.3, P = .0097) and combined (7.7 ± 7.2, P = .015) groups. The improvement in mean EAT-10 score did not remain statistically significant among those treated with thyroplasty (5.5 ± 4.6, P = .1563) at the second postoperative visit (Figure 1). There was no significant difference, however, between thyroplasty and injection medialization groups at the first or second follow-up visits (P = .1569 and P = .9301, respectively). Of the 30 patients with abnormal preoperative EAT-10 scores, 6 reported scores within the normal range (<3) at the second postoperative visit.

The mean preoperative VHI-10 scores for the thyroplasty, injection medialization, and combined groups were 25.8 ± 7.2, 26.5 ± 7.9, and 26.3 ± 7.6, respectively. There were statistically significant improvements in mean VHI-10 score at the first postoperative visit in the thyroplasty (19.8 ± 9.0, P = .0352), injection medialization (19.4 ± 9.4, P = .0007), and combined (19.7 ± 9.4, P = .0002) groups. The mean VHI-10 score remained significantly improved at the second postoperative visit in the thyroplasty (16.6 ± 10.4, P = .0469), injection medialization (16.3 ± 9.3, P = .0002), and

combined (16.5 ± 19.6, P = .0001; Figure 2) groups. There was no significant difference between thyroplasty and injection medialization groups at the first or second follow-up visits (P = .7029 and P = .5064, respectively).

While the idiopathic group had a higher mean preoperative EAT-10 score than the iatrogenic group (14.5 ± 12.4 vs 9.25 ± 12.4, respectively), there was no significant difference in response to treatment (P = .1772). Similarly, the idiopathic and iatrogenic groups showed no significant difference in VHI-10 scores following medialization (18.3 ± 9.8 vs 19.6 ± 8.4, P = .74).

Discussion

Glottal competence plays a critical role in safe swallowing. Both injection medialization and medialization thyroplasty have been shown to decrease Penetration-Aspiration Scale scores on videofluoroscopy. However, the effect of VFM on patient-described swallowing impairment has not been previously reported. In this investigation, greater than two-thirds of patients with UVFI reported dysphagia symptoms. This is comparable to previous studies, which suggest between 50% and 61% of those with UVFI may present with some degree of swallowing dysfunction. Data from this investigation suggest that dysphagia is common in persons with UVFI and that VFM improves, but does not completely eliminate, dysphagia symptoms. Twenty percent of the patients with abnormal preoperative EAT-10 achieved a score within the normal range postoperatively. The mean EAT-10 score improved nearly 5 points, although the majority of patients with abnormal baseline scores continued to report symptoms postoperatively. Previous work from our center suggests that patients with UVFI also have comorbid pharyngeal weakness. The reduction but not elimination of dysphagia reported in this investigation supports this finding and suggests that glottal competence is not the sole etiology of dysphagia in patients with UVFI.

The findings of this study also suggest that the impact of VFM on dysphagia is durable across multiple follow-up visits, with a mean follow-up of approximately 4 months. Given the observed improvement in self-reported dysphagia symptoms following VFM, medialization may be considered a reasonable initial therapeutic option in patients with UVFI before further interventions for dysphagia are pursued. Investigation with longer follow-up is necessary to confirm prolonged durability of symptomatic improvement.

The limitations in this investigation include those intrinsic to a retrospective review. The patient population consists of only those patients with UVFI who have elected to undergo surgery, potentially selecting for higher preoperative scores on patient-reported symptom indices. In this study, a preponderance of patients opted to undergo injection medialization. The postoperative edema and potential for temporary worsening of swallowing dysfunction following open thyroplasty in short-term follow-up may account for the lack of statistical improvement in this group at the second follow-up visit. The relatively small numbers of patients in the thyroplasty group at the second follow-up may also have weakened the statistical analysis at the subgroup level. Loss to follow-up after the first postoperative visit occurred in approximately one-third of patients in this study, which could limit conclusions regarding durability of treatment effect. A prospective investigation with a larger sample size is indicated to confirm these results.

Conclusion

Patients with UVFI commonly suffer from dysphagia and report significant improvement in swallowing symptoms following VFM. These outcomes are accompanied by improvement in self-reported voice quality and appear to be durable over time.
